Description

BACKGROUND OF THE INVENTION

5 Technical Field

[0001] The present invention relates to an encryption circuit for implementing in hardware the Rijndael algorithm, which is the next generation common key block encryption standard, known as the AES (advanced encryption standard), and will replace the current common key block encryption standard in the US, called DES.

10 Description of Related Art

[0002] A great variety of services are being considered that involve the Internet, including electronic commerce and electronic money. These technologies are used not just in the daily lives of individuals, but also in a wide range of fields, including transactions among corporations and improving productivity. In particular, it is expected that encryption functions will be loaded onto smart cards and mobile handsets, for the purpose of verifying the identity of individuals, and that these technologies will be widely used for authentication, digital signatures, and data encryption.

[0003] Common key cryptography is used in these applications to prevent third parties from tapping on the Internet. The current standard adopted in the US for common key cryptography is DES; as its replacement, the AES (advanced encryption standard), known as the Rijndael algorithm, has been selected to be next generation common key block cryptography standard, and this algorithm is becoming the new standard. (The AES draft is available at <http://csrc.nist.gov/publications/drafts/drips-AES.pdf>)

[0004] AES is a block cipher for processing in block lengths of 128 bits, and the encryption algorithm, as shown in FIG. 1, is thought to be executable by an encryption circuit comprising a round function unit 20 and a key schedule unit 10. The round function unit 20 comprises an input register 21 that temporarily stores input data, an XOR processing unit 22 that XORs the input data and expanded key segment, a round processing unit 23, a final round processing unit 24 and an output register 25 that temporarily stores output data.

[0005] The round processing unit 23 comprises a Byte Sub transformation unit 31, a Shift Row transformation unit 32, a Mix Column transformation unit 33 and a Round Key Addition unit 34; the final round processing unit 24 performs the processing of the round processing unit 23 except for the Mix Column transformation 33; it comprises a Byte Sub transformation unit 35, a Shift Row transformation unit 36 and a Round Key Addition unit 37.

[0006] Round processing iterated; the number of rounds N_r including the final round depends on the key length inputted into the key schedule unit 10, and is defined as shown in Table 1.

[Table 1]

Key Length and Number of Rounds	
Key Length	N_r
128bit	10
192bit	12
256bit	14

[0007] Thus for each key length round processing is executed N_r-1 times, and at the end the final round processing is executed. When the key length is 128 bits, round processing is executed 9 times; when 192 bits, 11 times; and when 256 bits, 13 times; and then in each case the final round processing is executed. Round keys generated at the key schedule unit 10 are inputted into the XOR processing unit 22, round processing unit 23 and final round processing unit 24.

[0008] The key schedule unit 10 generates round keys based on the key generation schedule specified in the AES draft; that algorithm is shown in FIG. 2.

[0009] The AES Proposal specification (AES Proposal: Rijndael, at <http://csrc.nist.gov/encryption/aes/rijndael/Rijndael.pdf>) introduces 2 hardware implementations for AES block cipher circuits.

[0010] One of these is a method for hardware implementation, in 128 bit units, of all the functions shown in FIG. 1 as they are (hereinafter, "conventional example 1"). In this case, for encryption and decryption, the order of processing of the functions is reversed, and thus it is necessary to prepare separate processing circuits for encryption and decryption.

[0011] Also, because, as shown in Table 1, it is necessary to change the number of times round processing is exe-

EP 1 271 839 A2

cutted depending upon the key length, it is necessary to create circuits for each key length.

[0012] Furthermore, because of the reversal of order between encryption and decryption, the order of key generation in the key schedule unit 10 for the round keys used in the round function unit 20 has to be reversed between encryption and decryption. Therefore, either there has to be 2 separate key schedule units, for encryption and for decryption, or a method has to be devised for using the key schedule unit 10 for both encryption and decryption.

[0013] The second method, as shown in FIG. 3, involves creating a coprocessor 50 that has a Byte Sub transformation unit 51 and a Mix Column transformation unit 52, and implementing in hardware only the Byte Sub transformation and the Mix Column transformation functions, and having all other functions incorporated as software into a program 41, and then processing with a CPU 40 (hereinafter, "conventional example 2").

[0014] In this case, Byte Sub transformation and Mix Column transformation, which are unsuited for processing by the CPU 40 for reasons of processing time, are implemented in hardware as the coprocessor 50, and the other processing is processed by the program 41 stored in the CPU, thus allowing the circuit scale to be reduced.

[0015] If we suppose that the AES block cipher is to be incorporated into a smart card or the like, the functions required of an encryption circuit would be to maintain a certain level of processing speed, while keeping the scale of the circuit small. With these requirements, the conventionally proposed method of implementing all the functions in 128-bit units results in the scale of circuit being too large, making the loading thereof onto a smart card difficult. With the method of implementing in hardware only the Byte Sub transformation and the Mix Column transformation, and processing the other functions with software, there is the problem of the processing speed requirements not being fulfilled.

[0016] Moreover, with the key schedule unit 10 that generates the round keys, if all the round keys are stored in memory, a large-capacity memory is needed, and this would make the scale of circuit large. Therefore, in order to reduce the scale of circuit without reducing processing speed, it is desirable to generate round keys with a circuit constitution that does not require storing the entire expanded key in memory.

SUMMARY OF THE INVENTION

[0017] It is an object of the present invention to present an encryption circuit that is small in scale and that can achieve a certain level of processing speed when implementing the AES block cipher.

[0018] The present invention provides an encryption circuit that generates from a cipher key a plurality of round keys having a number of bits corresponding to a predetermined processing block length and executing, for each processing block length, input data and round key encryption/decryption processing, by means of a round function unit comprising an XOR operation unit that XORs the input data and one of the round keys and a round processing unit that iterates round processing that includes Byte Sub transformation, Shift Row transformation, Mix Column transformation and Round Key Addition, wherein:

the round processing unit comprises: a first selector that segments input data into execution block lengths smaller than the processing block length; a first Round Key Addition circuit that adds the round key value to input data for each the execution block length; an intermediate register/Shift Row transformation circuit that temporarily stores the output of the first Round Key Addition circuit and executes Shift Row transformation using the processing block length; a Byte Sub transformation circuit wherein the intermediate register/Shift Row transformation circuit value is inputted for each the execution block length and Byte Sub transformation is executed; a second Round Key Addition circuit wherein the intermediate register/Shift Row transformation circuit value is inputted for each the execution block length and the round key value is added for each the execution block length; a Mix Column transformation circuit executing Mix Column transformation on the output of the second Round Key Addition circuit; and a second selector that outputs to the first Round Key Addition circuit one output from among the outputs of the first selector, intermediate register/Shift Row transformation circuit, Byte Sub transformation circuit, or Mix Column transformation circuit.

[0019] Here, the execution block length can be a multiple of 8 bits, the processing block length can be 128 bits and the execution block length can be 32 bits.

[0020] Further, the key length of the cipher key can be any of 128 bits, 192 bits or 256 bits.

[0021] Also, the Byte Sub transformation circuit can comprise a matrix operation unit for decryption that executes a matrix operation on input data; a third selector that outputs either the input data or the output of the matrix operation unit for decryption; an inverse operation unit for executing an inverse operation on the data outputted from the third selector; a matrix operation unit for encryption that executes a matrix operation on the data outputted from the inverse operation unit; and a fourth selector that outputs either the output of the inverse operation unit or the output of the matrix operation unit for encryption.

[0022] Further, the matrix operation unit for decryption and the matrix operation unit for encryption comprises an XOR circuit so as to perform 8-bit operations at one clock cycle and the matrix operation unit for decryption and the matrix operation unit for encryption comprises an XOR circuit so as to perform 1-bit operations at one clock cycle.

[0023] Also, the intermediate register/Shift Row transformation circuit can be used for both encryption and decryption

EP 1 271 839 A2

through the reversal of order of input of shift data relating to amount of shift for data to be inputted into the intermediate register/Shift Row transformation circuit, the input order for decryption being the reverse of the order for encryption.

[0024] Further, the Mix Column transformation circuit can comprise a plurality of multiplication units with unique multipliers and an XOR circuit that performs XOR operations for the plurality of multiplication units, the Mix Column transformation circuit executing a matrix operation between data inputted into each multiplication unit and the multiplier established for each multiplication unit. In this case, the Mix Column transformation circuit comprises 4 operation units having 4 multiplication units capable of 8-bit unit operations and XOR circuits that execute XOR operations based on the outputs of the 4 multiplication units. This multiplication units can control 2 multipliers and are used for both encryption and decryption and the multiplication units can be constituted to control addition values from high-order bits.

[0025] Also, an encryption circuit can be constituted so as to have a key expansion schedule circuit that generates from the cipher key, as an expanded key segmented into bit numbers corresponding to the execution block length, a plurality of round keys with bit numbers corresponding to a predetermined processing block length. The key expansion schedule circuit comprises:

- a fifth selector that segments a cipher key into the number of bits corresponding to the execution block length and outputs the same;
- a shift register to which flip-flop circuits are connected at a plurality of stages, the flip-flop circuits latching data in units of the execution block length;
- a first XOR circuit that XORs the output of the final stage flip-flop circuit of the shift register with one constant selected from among a group of constants;
- a sixth selector into which are inputted the outputs of those flip-flops of the shift register that are involved in operations for encryption and the outputs of those flip-flops involved in operations for decryption, and which selectively outputs one of these;
- a Rot Byte processing circuit that rotates the output of the sixth selector;
- a seventh selector into which the output of the sixth selector and the output of the Rot Byte circuit is inputted and which selectively outputs one of these;
- a Sub Byte processing circuit that executes Byte Sub transformation on the output of the seventh selector for each the execution block length;
- an eighth selector into which the output of the sixth selector and the output of the Sub Byte processing circuit are inputted, and which selectively outputs one of these;
- a second XOR circuit that executes an XOR operation based on the output of the first XOR circuit and the output of the eighth selector; and
- a shift register unit selector that selectively outputs, to those flip-flops of the shift register the outputs of which are subject to operations for encryption, either the output of the second XOR circuit or the output of the adjacent stage flip-flop.

[0026] Here, the shift register comprises 8 flip-flops executing data processing in 32-bit units, and the sixth selector is constituted so that the outputs of the second, fourth, sixth and eighth flip-flops from the bottom from among the flip-flops are inputted therein, and that it outputs one of these.

[0027] Also, through the input into the seventh selector of the output of the intermediate register/Shift Row transformation circuit and the input into the second selector of the output of the Sub Byte processing circuit, a single circuit can be used for the Sub Byte processing circuit and the Byte Sub transformation circuit of the round processing unit.

[0028] From the following detailed description in conjunction with the accompanying drawings, the foregoing and other objects, features, aspects and advantages of the present invention will become readily apparent to those skilled in the art.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS**Round Function Unit**

[0030] The AES block cipher is an algorithm that encrypts/decrypts the 128 bit data with the 128 bit, 192 bit or 256 bit key. As shown in FIG. 1, it comprises a key schedule unit 10 that generates a plurality of round keys from the cipher key, and a round function unit 20 that uses the round keys inputted from the key schedule unit 10 to encrypt and decrypt. The round function unit 20 performs such processing as XOR operations, Byte Sub transformation processing, Shift Row transformation processing, Mix Column transformation processing, Round Key Addition processing.

[0031] The first embodiment of the present invention is a circuit for implementation of this round function unit 20, and the constitution of this circuit is shown in FIG. 4. Each circuit block executes 32-bit processing with the exception of Shift Row transformation processing, which is 128-bit processing; transfer of data between circuit blocks is executed in 32-bit units.

[0032] This round function unit contains: an input register 201 that temporarily stores input data; a first selector 202 that selects 32-bit data from the 128-bit input data; a second selector 203 into one input terminal of which the output of the first selector 202 is inputted; a first Round Key Addition circuit 204 into which the output of the second selector 203 is inputted; an add data selector 205 that inputs into the first Round Key Addition circuit 204 an expanded key segment or "0"; an intermediate register/Shift Row transformation circuit 206 that stores the output value of the first Round Key Addition circuit 204 and executes Shift Row transformation in 128-bit units; a Byte Sub transformation circuit 207 into which intermediate register/Shift Row transformation circuit 206 values are inputted and which executes Byte Sub transformation; a second Round Key Addition circuit 208 into which intermediate register/Shift Row transformation circuit 206 values are inputted for each 32 bits; an add data selector 209 which inputs into the second Round Key Addition circuit 208 an expanded key segment or "0"; and a Mix Column transformation circuit 210 which executes Mix Column transformation on the output of the second Round Key Addition circuit 208. The outputs of the first selector 202, Byte Sub transformation circuit 207, Mix Column transformation circuit 210, and intermediate register/Shift Row transformation circuit 206 are inputted into the second selector 203, and one of these outputs is outputted to the first Round Key Addition circuit 204.

Operation Schedule during Encryption

[0033] The operation schedule during encryption in the round function unit is shown in Table 2.

EP 1 271 839 A2

[Table 2] Round Function Operation Schedule

Round	Cycle	Processing	SEL_B
0	000-003	Round Key Addition	a
1	004-007	Byte Sub Transformation	b
	008	Shift Row Transformation	c
	009-012	Mix Column Transformation Round Key Addition	c
2	013-016	Byte Sub Transformation	b
	017	Shift Row transformation	c
	018-021	Mix Column Transformation Round Key Addition	c
	Omitted		
Nr-1	#1	Byte Sub Transformation	b
	(Nr-1)*9-1	Shift Row Transformation	c
	(Nr-1)*9 - (Nr-1)*9+3	Mix Column Transformation Round Key Addition	c
Nr	#2	Byte Sub Transformation	b
	Nr*9-1	Shift Row Transformation	d
	Nr*9 - Nr*9+3	Round Key Addition	d

#1: (Nr-1)*9-5 - (Nr-1)*9-2
 #2: Nr*9-5 - Nr*9-2

Note: The table shows operations during encryption.
 In decryption, the order of round key and Mix
 Column processings is switched.

[0034] Here, in round 0, addition of an expanded key segment is executed by the first Round Key Addition circuit 204 with a selector position of "a" for the second selector 203. Input data in the input register 201 is selected in 32 bit units by the first selector 202 and inputted into the first Round Key Addition circuit 204, and to this is added a portion of a round key, inputted from the key schedule unit, this portion being a 32-bit segment of the expanded key. While the input data and the expanded key are being changed into 32-bit units, the first Round Key Addition circuit 204 executes addition processing, and the XOR processing of the XOR unit 22 in FIG. 1 is thereby executed on 128-bit processing blocks in the 4 cycles of cycles 000 through 003. The result of the operation by the first Round Key Addition circuit 204 is stored in order in 32-bit units in the intermediate register/Shift Row transformation circuit 206.

[0035] In round 1, the round processing 23 in FIG. 1 is executed, and Byte Sub transformation processing 31, Shift Row transformation processing 32, Mix Column transformation processing 33, and Round Key Addition processing 34 are executed. Thus, first of all, in cycles 004 through 007, with a selector position of "b" for the second selector 203,

EP 1 271 839 A2

the data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the Byte Sub transformation circuit 207. At this time, by making the data to be selected by the add data selector 205 "0", the first Round Key Addition circuit 204 is put into a masked state. The result of the operations of Byte Sub transformation circuit 207 is stored in order in 32-bit units in the intermediate register/Shift Row transformation circuit 206. Thus Byte Sub transformation processing performs on 128 bits, and the result is stored in the intermediate register/Shift Row transformation circuit 206.

[0036] Next, in cycle 008, Shift Row transformation processing is executed. The intermediate register/Shift Row transformation circuit 206 is capable of executing Shift Row transformation processing in 128-bit units, and in this cycle 008, 128-bit Shift Row transformation processing is executed. At this time, the selector position of the second selector 203 may be any position, but in consideration of the processing in the next cycle, a position of "c" is preferable.

[0037] In cycles 009 through 012, Mix Column transformation processing and Round Key Addition processing are executed. Herein, the data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the second Round Key Addition circuit 208. At this time, by making the data to be selected by the add data selector 209 "0", the second Round Key Addition circuit 208 is put into a masked state. By setting the selector position of the second selector 203 at "c", the data upon which Mix Column transformation processing has been executed at the Mix Column transformation circuit 210 is inputted into the first Round Key Addition circuit 204 via the second selector 203. An expanded key segment to be inputted from the key schedule unit is selected for data to be selected by the add data selector 205, and this data undergoes Round Key Addition processing at the first Round Key Addition circuit 204. The result of the Mix Column transformation processing at the Mix Column transformation circuit 210 and the Round Key Addition processing at the first Round Key Addition circuit 204 are, while being each shifted in 32-bit units, stored in the intermediate register/Shift Row transformation circuit 206. Thus, the result of the 128 bits upon which Mix Column transformation processing and the Round Key Addition processing were executed in cycles 009 through 012 are stored in the intermediate register/Shift Row transformation circuit 206. In this manner, one round of processing is executed in the 9 cycles of cycles 004 through 012.

[0038] Next, in rounds 2 through (Nr-1), the same processing as in round 1 is executed (however, Nr is the number of processing rounds including the final round, and as shown in Table 1, the number of rounds will differ according to key length).

[0039] In round Nr (the final round), the final round processing 24 of FIG. 1 is executed; this comprises Byte Sub transformation processing 35, Shift Row transformation processing 36 and Round Key Addition processing 37.

[0040] Thus in cycles (Nr*9-5) through (Nr*9-2), with the selector position of the second selector 203 at "b", data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the Byte Sub transformation circuit 207. At this time, by making the data to be selected by the add data selector 205 "0", the first Round Key Addition circuit 204 is put into a masked state. The result of the operation of the Byte Sub transformation circuit 207 is stored in order in 32-bit units in the intermediate register/Shift Row transformation circuit 206. Thus Byte Sub transformation processing of 128 bits is performed, and the result is stored in the intermediate register/Shift Row transformation circuit 206.

[0041] Next, in the (Nr*9-1) cycle, 128-bit Shift Row processing is executed. At this time, the selection position of the second selector 203 may be any position, but in consideration of the processing of the next cycle, a position of "d" is preferable.

[0042] In the (Nr*9) through (Nr*9+3) cycles, Round Key Addition processing is executed. Specifically, by making the selector position of the second selector 203 "d", the data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the first Round Key Addition circuit 204 via the second selector 203. At this time, by making data to be selected by the add data selector 205 an expanded key segment to be inputted from the key schedule unit, the first Round Key Addition circuit 204 adds 32-bit round keys. The result of the Round Key Addition processing by the first Round Key Addition circuit 204 is stored in the intermediate register/Shift Row transformation circuit 206 while being shifted in 32-bit units. Thus in the (Nr*9) through (Nr*9+3) cycles, the result of the Round Key Addition processing on the 128 bits is stored in the intermediate register/Shift Row transformation circuit 206. In this manner, in the 9 cycles from (Nr*9-5) through (Nr*9+3), final round processing is executed.

Operation Schedule during Decryption

[0043] Operations during decryption in this round function unit are performed in the reverse order to operations during encryption. This operation schedule is shown in Table 3.

EP 1 271 839 A2

[Table 3]

Round Function Operation Schedule

Round	Cycle	Processing	SEL_B
0	000-003	Round Key Addition	a
1	004	Shift Row Transformation	b
	005-008	Byte Sub Transformation	b
	009-012	Round Key Addition	c
		Mix Column Transformation	
2	013	Shift Row Transformation	b
	014-017	Byte Sub Transformation	b
	018-021	Round Key Addition	c
		Mix Column Transformation	
	Omitted		
Nr-1	(Nr-1)*9-5	Shift Row Transformation	b
	#1	Byte Sub Transformation	b
	(Nr-1)*9 -	Round Key Addition	c
	(Nr-1)*9+3	Mix Column Transformation	
Nr	Nr*9-5	Shift Row Transformation	b
	#2	Byte Sub Transformation	b
	Nr*9 -	Round Key Addition	d
	Nr*9+3		

#1: (Nr-1)*9-4 - (Nr-1)*9-1

#2: Nr*9-4 - Nr*9-1

[0044] In round 0, with the selector position of the second selector 203 at "a", the first Round Key Addition circuit 204 adds expanded key segments. Input data in the input register 201 is selected in 32-bit units by the first selector 202 and inputted into the first Round Key Addition circuit 204, and from the round key to be inputted from the key schedule unit, a 32-bit expanded key segment is added. At this time, data to be inputted via the first selector 202 is inputted in an order that is the reverse of the input order for encryption, and the input order of the expanded key segments to be inputted from the key schedule input is also the reverse of the input order for encryption. In this manner, as the input data and expanded key are changed every 32 bits, the first Round Key Addition circuit 204 executes add processing, thereby allowing execution of Round Key Addition processing on a 128-bit processing block in cycles 000 through 003. The result of the operations of the first Round Key Addition circuit 204 is stored in 32-bit units in the intermediate register/Shift Row transformation circuit 206.

[0045] In round 1, processing is performed in the order of Shift Row transformation, Byte Sub transformation, Round Key Addition, and Mix Column transformation. For this reason, first, in cycle 004, in the intermediate register/Shift Row transformation circuit 206, Shift Row transformation processing is executed in 128-bit units. In this case the processing is the same as the Shift Row transformation processing during encryption. Also, the selector position of the second selector 203 may be any position, but in consideration of the processing in the next cycle, a position of "b" is preferable.

[0046] Next, in cycles 005 through 008, with a selector position of "b" for the second selector 203, data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the Byte Sub transformation circuit 207. At this time, by making the data to be selected by the add data selector 205 "0", the first Round Key Addition circuit 204 is put into a masked state. The result of the operation by the Byte Sub transformation circuit 207 is stored in order in the intermediate register/Shift Row transformation circuit 206 in 32-bit units. In this case, the Byte Sub transformation processing is executed so as to be the inverse of the transformation processing during encryption; this will be discussed below. In this manner, Byte Sub transformation processing is performed on 128 bits, and the result is stored in the intermediate register/Shift Row transformation circuit 206.

[0047] In cycles 009 through 012, Round Key Addition processing and Mix Column transformation processing are executed. Here, data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the second Round Key Addition circuit 208. At this time, data selected by the add data selector 209 is made the expanded key segment inputted from the key schedule unit. Also, with the selector position of the second selector 203 at "c", the output of the Mix Column transformation circuit 210 is inputted into the first Round Key Addition circuit 204 via the second selector 203. At this time, by making the data to be selected by the

EP 1 271 839 A2

add data selector 205 "0", the first Round Key Addition circuit 204 is put into a masked state. In this case, Mix Column transformation processing is executed in such a manner as to be transformation processing that is the inverse of the transformation processing during encryption; this will be explained in detail below. Thus the 128-bit resultant of the Round Key Addition processing by the second Round Key Addition circuit 208 and of the Mix Column transformation processing by the Mix Column transformation circuit 210 is stored in the intermediate register/Shift Row transformation circuit 206. In this manner, one round of processing is executed in the 9 cycles of cycle 004 through 012.

[0048] Next, in rounds 2 through (Nr-1), the same processing as in round 1 is executed (however, Nr is the number of rounds including the final round, and as shown in Table 1, different numbers of rounds are stipulated depending on key length).

[0049] In round Nr (the final round), Shift Row transformation processing, Byte Sub transformation processing and Round Key Addition processing are executed.

[0050] For this reason in cycle (Nr-5), 128-bit Shift Row transformation processing is executed. At this time, the selector position of the second selector 203 may be any position, but in consideration of the processing of the next cycle, a position of "b" is preferable.

[0051] Next, in cycles (Nr-4) through (Nr-1), with the selector position of the second selector 203 at "b", data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the Byte Sub transformation circuit 207. At this time, by making the data to be selected by the 205 "0", the first Round Key Addition circuit 204 is put into a masked state. Result of the operation by the Byte Sub transformation circuit 207 is stored in order in the intermediate register/Shift Row transformation circuit 206 in 32-bit units. Thus Byte Sub transformation processing is conducted on 128 bits, and the result is stored in the intermediate register/Shift Row transformation circuit 206.

[0052] In cycles (Nr-9) through (Nr-6), Round Key Addition processing is executed. Here, by making the selector position of the second selector 203 "d", data stored in the intermediate register/Shift Row transformation circuit 206, while being shifted in 32-bit units, is read out and inputted into the first Round Key Addition circuit 204 via the second selector 203. At this time, by making the data to be selected by the add data selector 205 an expanded key segment inputted from the key schedule unit, 32-bit Round Key Addition processing by the first Round Key Addition circuit 204 can be executed. The result of the Round Key Addition processing in the first Round Key Addition circuit 204 is, while being shifted in 32-bit units, stored in the intermediate register/Shift Row transformation circuit 206. Thus in cycles (Nr-9) through (Nr-6), the 128-bit result of Round Key Addition processing is stored in the intermediate register/Shift Row transformation circuit 206. In this manner, the final round processing is executed in the 9 cycles from cycles (Nr-9-5) through (Nr-6-3). Intermediate Value Register/Shift Row Transformation Circuit

[0053] FIG. 5 shows one embodiment of the intermediate value register/Shift Row transformation circuit.

[0054] In this constitution, 4 shift registers that process in 8-bit units are provided. The first shift register has 4 flip-flops, flip-flops 302, 304, 306 and 308, connected in series, and to each of the flip-flops 302, 304, 306, and 308 selectors 301, 303, 305, and 307, which select inputs, are respectively connected. Input data IN0 and the output of the flip-flop 302 are inputted into the first selector 301, and either one of these is inputted into the flip-flop 302. Similarly, into the second through fourth selectors 303, 305 and 307, the outputs of the previous-stage flip-flops 302, 304, and 306, as well as the outputs of the flip-flops 304, 306, and 308 are inputted, and one of these is inputted into the flip-flops 304, 306 and 308, respectively.

[0055] The second shift register has 4 flip-flops, flip-flops 312, 314, 316 and 318 connected in series; and to each of the flip-flops 312, 314, 316 and 318, selectors 311, 313, 315, and 317, which select input, are respectively connected. Input data IN1 and the outputs of the flip-flop 312 and the flip-flop 318 are inputted into the first selector 311, and one of these is inputted into the flip-flop 312. Similarly, into the second through fourth selectors 313, 315 and 317, the outputs of the previous-stage flip-flops 312, 314, and 316, as well as the outputs of the flip-flops 314, 316, and 318 are inputted, and one of these is inputted into the flip-flops 314, 316 and 318, respectively.

[0056] The third shift register has 4 flip-flops, flip-flops 322, 324, 326 and 328 connected in series; and to each of the flip-flops 322, 324, 326 and 328, selectors 321, 323, 325, and 327, which select input, are respectively connected. Input data IN2 and the outputs of the flip-flop 322 and the flip-flop 326 are inputted into the first selector 321, and one of these is inputted into the flip-flop 322. Similarly, into the second selector 323, the output of the respective previous-stage flip-flop 322, the output of the flip-flop 324, and the output of the flip-flop 328 are inputted; and one of these is inputted into the flip-flop 324. Into the third selector 325, the output of the previous stage flip-flop 324, the output of the flip-flop 326, and the output of the flip-flop 322 are inputted, and one of these is inputted into the flip-flop 326. Into the fourth selector 327, the output of the previous stage flip-flop 326, the output of the flip-flop 328 and the output of the flip-flop 324 are inputted, and one of these is inputted into the flip-flop 328.

[0057] The fourth shift register has 4 flip-flops, flip-flops 332, 334, 336 and 338 connected in series; and to each of the flip-flops 332, 334, 336 and 338, selectors 331, 333, 335, and 337, which select input, are respectively connected. Input data IN3 and the outputs of the flip-flop 332 and the flip-flop 334 are inputted into the first selector 331, and one of these is inputted into the flip-flop 332. Similarly, into the second selector 333, the output of the previous-stage flip-

EP 1 271 839 A2

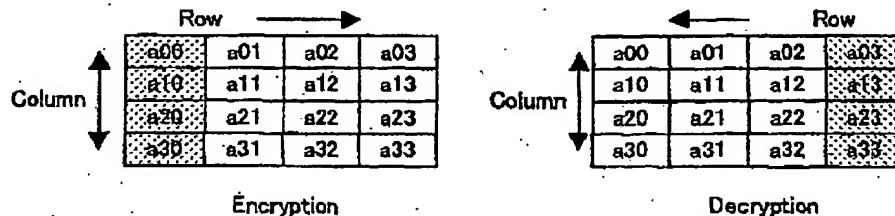

flop 332, the output of the flip-flop 334, and the output of the flip-flop 336 are inputted, and one of these is inputted into the flip-flop 334. Into the third selector 335, the output of the previous stage flip-flop 334, the output of the flip-flop 336, and the output of the flip-flop 338 are inputted, and one of these is inputted into the flip-flop 336. Into the fourth selector 337, the output of the previous stage flip-flop 336, the output of the flip-flop 338, and the output of the flip-flop 332 are inputted, and one of these is inputted into the flip-flop 338.

[0058] When an intermediate value register/Shift Row transformation circuit thus constituted is operated as an intermediate value register for the various processing stages, by inputting data into input data IN0 through IN3 in 8-bit units, data processed in each cycle in 32-bit units can be stored. Furthermore, by making the selector positions of the selectors 301 through 337 "b", and, while shifting the data in flip-flops to the next stage, inputting data in 8-bit units into input data IN0 through IN3 respectively, 128 bits of data can be inputted in 4 cycles. When the input of 128 bits of data has been completed, the 4 8-bit data inputted in the first cycle are latched in the flip-flops 308, 318, 328, and 338, respectively.

[0059] An explanation will now be given of the operations of the Shift Row transformation.

[0060] In the Rijndael algorithm, input data is segmented into 8-bit data segments a00 through a33 and these are processed as a matrix; the direction of the shift for decryption is the reverse of the direction for encryption. In the present invention, the order in which data is processed is the order of the column array; by processing in reverse order for encryption and for decryption, Shift Row transformation can be achieved using the same processing.

[Table 4] Data Array and Processing Order

[0061] As shown on Table 4 left, when the data in rows is arranged in order starting from the column to the far left, for encryption, processing is executed starting from the column to the far left. For decryption, as seen in Table 4 right, processing is executed starting from the column to the far right.

[0062] In Shift Row transformation processing for encryption, the rows of a data array arranged as on Table 4 left are cyclically shifted different byte-lengths. Specifically, as shown in Table 5, the first row is not shifted, row 2 is cyclically shifted one byte to the left, row 3 is cyclically shifted 2 bytes to the left, and row 4 is cyclically shifted 3 bytes to the left. This causes the pre-processing state, shown in Table 5 left, to become the post-processing state shown in Table 5 right.

[Table 5]

				a22	a23	a20	a21
				a33	a30	a31	a32

EP 1 271 839 A2

[0063] For decryption, so as to achieve the inverse of the processing during encryption, the rows of a data array arranged as on Table 4 left are cyclically shifted different byte-lengths. Specifically, as shown in Table 5, the first row is not shifted, row 2 is cyclically shifted 3 bytes to the left, row 3 is cyclically shifted 2 bytes to the left, and row 4 is cyclically shifted 1 byte to the left. This causes the pre-processing state, shown in Table 6 left, to become the post-processing state shown in Table 6 right.

[Table 6]

[Decryption]

a13	a10	a11	a12
a22	a23	a20	a21
a31	a32	a33	a30

[0064] In the present embodiment, the intermediate value register/Shift Row transformation circuit shown in FIG. 5 is used. Thus, at the stage when the input of 128 bits of data has been completed, the data that was inputted in the initial cycle is latched in the final stage flip-flops 308, 318, 328, and 338, and data is latched in order in the previous stage flip-flops. When data is to be outputted, as it is being shifted 1 byte to the right at one cycle, data is outputted from the final stage flip-flops at the far right. Therefore when data is rearranged in consideration of the fact that the data processing order starts from the far right, the state before Shift Row processing for encryption takes the form shown in Table 7 left.

[Table 7]

[Encryption]

Pre-processing

a03	a02	a01	a00
a13	a12	a11	a10
a23	a22	a21	a20
a33	a32	a31	a30

Cyclic Shift 1 Byte Right

Cyclic Shift 2 Bytes Right

Cyclic Shift 3 Bytes Right

Post-processing

a03	a02	a01	a00
a10	a13	a12	a11
a21	a20	a23	a22
a32	a31	a30	a33

[0065] To perform the same cyclic shift as in Table 5, as shown in Table 7 right, the first row is not shifted, the second row is cyclically shifted 1 byte to the right, the third row is cyclically shifted 2 bytes to the right, and the fourth row is cyclically shifted 3 bytes to the right.

[0066] In order to perform this kind of Shift Row transformation processing for encryption, the intermediate value register/Shift Row transformation circuit shown in FIG. 5 is used to switch and control the selectors, and to replace data at once, in 128-bit units.

[0067] For the first row, because a shift is unnecessary, the selector positions of the selectors 301, 303, 305 and 307 are set at "a". For the second row, because of the cyclic shift 1 byte to the right, the selector position of the selector 311 is set at "c", and the other selectors 313, 315, and 317 are set at selector position "b". For the third row, because of the cyclic shift 2 bytes to the right, the selector position of the selectors 321, 323, 325 and 327 is set at "c". For the fourth row, because of the cyclic shift 3 bytes to the right, the selector position of the selectors 331, 333, 335 and 337 is set at "c".

[0068] By designating the output data being latched by the flip-flops in the intermediate value register/Shift Row transformation circuit prior to execution of the above-described Shift Row transformation processing as b00 through

EP 1 271 839 A2

b33 respectively, as shown in FIG. 5 the output data becomes latched to the output of the flip-flops in an array as shown in Table 8 right.

[Table 8]

Shift Row Transformation Operation Model

Prior to Shift Row					Subsequent to Shift Row			
b03	b02	b01	b00	→	b03	b02	b01	b00
b13	b12	b11	b10		b10	b13	b12	b11
b23	b22	b21	b20		b21	b20	b23	b22
b33	b32	b31	b30		b32	b31	b30	b33

[0069] For decryption, because processing is executed from the right column as in Table 4, the data is arrayed as shown in Table 9 left.

[Table 9]

[Decryption]

Pre-processing					Post-processing			
a00	a01	a02	a03	Cyclic Shift 1 Byte Right	a00	a01	a02	a03
a10	a11	a12	a13		a13	a10	a11	a12
a20	a21	a22	a23		a22	a23	a20	a21
a30	a31	a32	a33		a31	a32	a33	a30

[0070] To perform the same cyclic shift as in Table 6, as shown in Table 9 right, the first row is not shifted, the second row is cyclically shifted 1 byte to the right, the third row is cyclically shifted 2 bytes to the right, and the fourth row is cyclically shifted 3 bytes to the right.

[0071] Therefore, as during the above-described Shift Row transformation for encryption, by setting the selector values of the selectors in the intermediate value register/Shift Row transformation circuit and performing exactly the same processing as the cyclic shift for encryption as shown in Table 8, Shift Row transformation processing for decryption can be executed.

[0072] In this way, the same intermediate value register/Shift Row transformation circuit can be used for Shift Row transformation processing for both encryption and decryption. Mix Column Transformation Circuit

[0073] The Mix Column transformation circuit adopted in this embodiment is shown in FIG. 6.

[0074] This Mix Column transformation circuit includes 4 operation units, a first operation unit 351, a second operation unit 352, a third operation unit 353 and a fourth operation unit 354. The first operation unit 351 comprises a first multiplication unit 361, a second multiplication unit 362, a third multiplication unit 363, and a fourth multiplication unit 364, each of which executes operations in 8-bit units, and an XOR circuit 365 that XORs the outputs of the multiplication units 361 through 364. The second operation unit 352, third operation unit 353, and the fourth operation unit 354, which are not shown in the figure, also have a first through fourth multiplication unit and an XOR circuit.

[0075] When a column j comprising (a0j, a1j, a2j, a3j) is transformed into a column comprising (b0j, b1j, b2j, b3j), the data (b0j, b1j, b2j, b3j) of column j after transformation can be expressed as follows.

EP 1 271 839 A2

Encryption

[0076]

5

$$b0j = 02 \cdot a0j + 03 \cdot a1j + 01 \cdot a2j + 01 \cdot a3j$$

10

$$b1j = 01 \cdot a0j + 02 \cdot a1j + 03 \cdot a2j + 01 \cdot a3j$$

$$b2j = 01 \cdot a0j + 01 \cdot a1j + 02 \cdot a2j + 03 \cdot a3j$$

15

$$b3j = 03 \cdot a0j + 01 \cdot a1j + 01 \cdot a2j + 02 \cdot a3j$$

Decryption

[0077]

20

$$b0j = 0E \cdot a0j + 0B \cdot a1j + 0D \cdot a2j + 09 \cdot a3j$$

25

$$b1j = 09 \cdot a0j + 0E \cdot a1j + 0B \cdot a2j + 0D \cdot a3j$$

$$b2j = 0D \cdot a0j + 09 \cdot a1j + 0E \cdot a2j + 0B \cdot a3j$$

30

$$b3j = 0B \cdot a0j + 0D \cdot a1j + 09 \cdot a2j + 0E \cdot a3j$$

[0078] The coefficients by which each column is multiplied are described as hexadecimal.

35

[0079] To execute this Mix Column transformation processing, the 32-bit data columns are inputted into the first through fourth operation units 351 through 354, respectively, and multiplication by the first through fourth operation units 361 through 364 and the operation by the XOR circuit are performed.

[0080] The multiplication units 361 through 364 of the operation units 351 through 361 are provided with a coefficient for encryption and a coefficient for decryption, so that they can be used for both encryption and decryption, and they are constituted so that selection of a coefficient can be made during operations.

40

[0081] The first multiplication unit 361 of the operation unit 351 can multiply inputted data by either 0x02 or 0x0E. The second multiplication unit 362 can multiply inputted data by either 0x03 or 0x0B. The third multiplication unit 363 can multiply inputted data by either 0x01 or 0x0D. The fourth multiplication unit 364 can multiply inputted data by either 0x01 or 0x09.

45

[0082] The first multiplication unit of the second operation unit 352 can multiply inputted data by either 0x01 or 0x09. The second multiplication unit can multiply inputted data by either 0x02 or 0x0E. The third multiplication unit can multiply inputted data by either 0x03 or 0x0B. The fourth multiplication unit can multiply inputted data by either 0x01 or 0x0D.

[0083] The first multiplication unit of the third operation unit 353 can multiply inputted data by either 0x01 or 0x0D. The second multiplication unit can multiply inputted data by either 0x01 or 0x09. The third multiplication unit can multiply inputted data by either 0x02 or 0x0E. The fourth multiplication unit can multiply inputted data by either 0x03 or 0x0B.

50

[0084] The first multiplication unit of the fourth operation unit 354 can multiply inputted data by either 0x03 or 0x0B. The second multiplication unit can multiply inputted data by either 0x01 or 0x0D. The third multiplication unit can multiply inputted data by either 0x01 or 0x09. The fourth multiplication unit can multiply inputted data by either 0x02 or 0x0E.

55

[0085] By changing the coefficients used for encryption and for decryption in the first through fourth multiplication units of the first through fourth operation units 351 through 354, the same circuit constitution can be shared for both encryption and decryption. Multiplication Units of the Mix Column Transformation Circuit

[0086] An example of the multiplication units included in the Mix Column transformation circuit is shown in FIG. 7.

[0087] The multiplication units multiply inputted 8-bit data (a7, a6, a5, a4, a3, a2, a1, a0) with a coefficient (b3, b2, b1, b0). For this, partial product operation units 375 through 378 are provided, which multiply the 8-bit data (a7, a6,

EP 1 271 839 A2

a5, a4, a3, a2, a1, a0) with each bit of a coefficient (b3, b2, b1, b0). Also provided are: an addition unit 371 that shifts the result of the partial product unit 376 1 bit and adds this to the result of the partial product unit 375, which multiplies using the highest bit of a coefficient; an addition unit 372 that shifts the resultant of the partial product unit 377 1 bit more over and adds this; and an addition unit 373 that shifts the resultant of the partial product unit 378 1 bit more over and adds this. There is also provided a division unit 374 into which the resultant of the addition unit 373 and overflow carried over from the addition units 371 to 373 are inputted and divided by a divisor.

[0088] With this constitution, by selectively setting as the coefficient (b3, b2, b1, b0) a coefficient for encryption and a coefficient for decryption, the mixed column transformation processing can be used both for encryption and for decryption.

[0089] As described above, there are 2 coefficients, set as (b3, b2, b1, b0), established for each multiplication unit. There are 4 combinations of coefficients in the multiplication units, namely, (0x02, 0x0E), (0x03, 0x0B), (0x01, 0x0D), (0x01, 0x09). When these are expressed as 4 low order bits, they become (0010, 1110), (0011, 1011), (0001, 1101), and (0001, 1001). The operations for common bits in these coefficients do not perform control of the partial products; rather, the operations for different bits control the addition processing; this allows the circuit to be reduced in scale.

[0090] For example, when the coefficients are the combination (0x01, 0x0D), they become (0001, 1101) when expressed in binary; by controlling whether or not the result of the addition of the partial product of the 2 upper bits is added to the partial product of the lower 2 bits, the selection and multiplication of 2 coefficients becomes possible. FIG. 8 shows the circuit constitution for the coefficient combination (0x01, 0x0D).

[0091] In FIG. 8, a first addition unit 381 that shifts inputted 8-bit data (a7, a6, a5, a4, a3, a2, a1, a0) 1 bit and executes addition processing thereupon. The output of the first addition unit 381 is inputted into a second addition unit 383 via a control logic circuit 382. This second addition unit 383 adds the result of the partial product operation by the uppermost bit of the coefficient, and it is constituted to shift inputted 8-bit data 3 bits and execute addition processing thereupon.

[0092] A division unit 384 is provided into which the resultant of the operation of the addition unit 383 and the overflow carried over from the first addition unit 381 and the second addition unit 383 are inputted and divided by a divisor.

[0093] The control logic circuit 382, when a coefficient is 0x01, does not output the output of the addition unit 381, which is an upper 2-bit resultant. The control logic circuit 382 may be constituted so that, when a coefficient is 0x0D, the output of the first addition unit 381, which is an upper 2 bit result, is outputted to the addition unit 383.

[0094] Because the multiplication performed here is multiplication over GF (2⁸) where the irreducible polynomial is $M(x) = x^8 + x^4 + x^3 + x + 1$, and the addition is over GF(2), they can be achieved with an XOR operation.

[0095] In this manner, by controlling the addition of partial products in different bits of 2 coefficients, the circuit scale can be made smaller, enabling reduction of the scale of circuit. Key Schedule Unit

[0096] FIG. 9 shows the circuit constitution of the key schedule unit.

[0097] The key schedule unit comprises, primarily, an expanded key generation logic unit 101, an expanded key register 120 and a key input register 131.

[0098] The key input register 131 is a 256-bit register comprising 8 32-bit registers k0 through k7, and a cipher key is stored in 32-bit units starting from register k0 and proceeding in order therefrom. When the cipher key is 256 bits, data is stored in all the registers k0 through k7; when the cipher key is 192 bits, data is stored in registers k0 through k5, and when the cipher key is 128 bits, data is stored in registers k0 through k3.

[0099] A selector 132 that selectively outputs one value from the registers k0 through k7 is connected to the key input register 131. This selector 132 selects 32 bits of data from the 256-bit data of the key input register 131 and inputs this at the lowest position of the expanded key register 120.

[0100] The expanded key register 120 is a shift register to which are connected in series 8 flip-flops 121 through 128, which are capable of processing in 32-bit units. Inputted into the flip-flop 128, which is at the lowest position, is the output of the selector 113, which selects the output of the selector 132 and the output of the expanded key generation logic unit 101. The output W7Key of the flip-flop 128 is inputted into the flip-flop 127. The output W6Key of the flip-flop 127 is inputted into the selector 112, which is at the stage previous to the flip-flop 128. Inputted into the selector 112 is the output W6KEY of the flip-flop 127 and the output of the expanded key generation logic unit 101, and one of these is inputted into the flip-flop 126.

[0101] The output W5KEY of the flip-flop 126 is inputted into the flip-flop 125. The output W4Key of the flip-flop 125 is inputted into the selector 111, which is at the stage previous to the flip-flop 124. Inputted into the selector 111 is the output W4KEY of the flip-flop 125 and the output of the expanded key generation logic unit 101, and one of these is inputted into the flip-flop 124.

[0102] The output W3KEY of the flip-flop 124 is inputted into the flip-flop 123. The output W2KEY of the flip-flop 123 is inputted into the flip-flop 122. The output W1KEY of the flip-flop 122 is inputted into the flip-flop 121.

[0103] The expanded key generation logic unit 101 includes a ROM 102 in which an expanded key generation constant Rcon is stored, an AND circuit 103 that ANDs a value read out from the ROM 102 and a signal RCON_EN, and an XOR circuit 104 which XORs the WOKEY of the flip-flop 121 positioned at the top of the expanded key register 120 and the output of the AND circuit 103, which have been inputted therein.

EP 1 271 839 A2

[0104] The expanded key generation logic unit 101 also includes a selector 105, into which the flip-flop 122 output W1KEY, the flip-flop 124 output W3KEY, the flip-flop 126 output W5KEY, and the flip-flop 128 output W7KEY are inputted, and which selectively outputs one of these. The output of the selector 105 is inputted into the Rot Byte circuit 106, which rotates data, the selector 107, and selector 109. The output of the Rot Byte circuit 106 and the output of the selector 105 are inputted into the selector 107, which supplies one of these to the Sub Byte circuit 108. The Sub Byte circuit 108 executes Byte Sub transformation processing in 32-bit portions, and supplies the output thereof to the selector 109. Into the selector 109 are inputted the output of the Sub Byte circuit 108 and the output of the selector 105, one of which it outputs. The expanded key generation logic unit 101 also includes an XOR circuit 110. The output of the XOR circuit 104 and the output of the selector 109 are inputted into the XOR circuit 110, which then XORs these outputs.

[0105] A key schedule unit thus constituted includes such functions as: 1) generation of the expanded key used in the Round Key Addition processing of the round function unit; 2) rewrite of the key input register during encryption, and setup of the expanded key initial value following completion of encryption and decryption; and 3) setup of expanded key initial value following rewrite of the key input register during decryption.

[0106] The round keys used in Round Key Addition processing of the round function unit must total 15, from the initial round key and round key 01 through round key 14, when the key length is 256 bits. Each round key is made up of 128 bits, in correspondence with the processing block length; in order to assign the round keys to the 32-bit expanded key segments generated by the key schedule unit, a total of 60 expanded key segments W00 through W59 are required. These expanded key segments W00 through W59 are used in the order W00→W59 for encryption, and in the order W59→W00 for decryption. In this embodiment, as shown in Table 10, expanded key segments are generated in the order W00→W59 for encryption, and in the order W59→W00 during decryption.

EP 1 271 839 A2

[Table 10] Expansion Key Schedule (This Example for 256-Bit Key Length)

No.	Encryption	Decryption

59	$W59 = W51 \wedge W58$	$W00 = W08 \wedge \text{Sub Byte}(\text{Rot Byte}(W07)) \wedge \text{Rcon}[1]$	

[0107] The expanded key segment W08 for encryption, in accordance with the formula $W08 = W00 \wedge \text{Sub Byte}(\text{Rot Byte}(W07)) \wedge \text{Rcon}[1]$, is obtained by XORing W00, Sub Byte(Rot Byte(W07)) and the constant Rcon[1]. Because $A \wedge A = A$, the expanded key segment W00 can be expressed as $W00 = W08 \wedge \text{Sub Byte}(\text{Rot Byte}(W07)) \wedge \text{Rcon}[1]$, meaning that W00 can be generated from W08 and W07. Thus, for decryption, first $W00 \Rightarrow W59$ are generated, and then in the order that is the inverse of encryption, i.e., $W59 \Rightarrow W00$, expanded key segments are generated. In this manner, there is no need to store all the expanded keys for decryption in memory, making possible decryption processing wherein only the expanded key segments needed for each round are generated.

[0108] An explanation will first be given of the generation of expanded key segments for the Round Key Addition function of the round function unit.

[0109] As shown in Table 10, in the Round Key Addition function in each round, 4 expanded key segments having 32 bits are used; because expanded key operations are performed in the background of the Mix Column transformation + Round Key Addition function of the round function, 4 expanded key segments may be created in 4 cycles. For this reason, in a circuit constitution as shown in FIG. 9, 1 expanded key segment is generated in 1 cycle. The expanded key segment register 120 comprises a shift register, and the expanded key segments currently being used in a round function use the output W0KEY of the flip-flop 121.

[0110] The selector 105 (SEL_B) of the expanded key generation logic unit 101, as shown in Table 11, is controlled so as to switch depending upon 2 different types of conditions, namely, key length and encryption/decryption. The selectors 111, 112, and 113 (SEL_E through SEL_G), into which the output of the expanded key generation logic unit 101 is inputted, are set based on key length, as shown in Table 12. However, when a cipher key is inputted as an initial value, "b" is selected as the selector position for the selectors 111 through 113. The selectors 107 and 109 (SEL_C, SEL_D), as shown in Table 13, are controlled so as to switch depending upon the expanded key generation logic. The ROM 102 stores the constant Rcon[i], which is inputted to the XOR circuit 104, and the constant Rcon[i] corresponding to the address "i" is stored as shown in Table 14.

[Table 11]

SEL_B Control		
Key length	Encryption	Decryption
128bit	W3KEY	W1KEY
192bit	W5KEY	W1KEY
256bit	W7KEY	W1KEY

[Table 12]

SEL_E through SEL_G Control			
Key length	SEL_E	SEL_F	SEL_G
128bit	a	b	b
192bit	b	a	b
256bit	b	b	a

[Table 13]

SEL_C, SEL_D Control			
Logic		SEL_C	SEL_D
Expanded key	$W[i] - W[i - Nk] \wedge W[i - 1]$	*	b
	$W[i] = W[i - Nk] \wedge \text{Sub Byte}(W[i - 1])$	b	a
	$W[i] = W[i - Nk] \wedge \text{Sub Byte}(\text{Rot Byte}(W[i - 1])) \wedge \text{Rcon}[i/Nk]$	a	a
Byte Sub		c	b
